Last time, we got to know correlated equilibria and coarse correlated equilibria. We showed that if all players use a no-external-regret algorithm to update their strategy choices, the average history of play will converge to a coarse correlated equilibrium. The only missing piece is: How do these algorithms work?

1 Problem Statement

There is a single player playing $T$ rounds against an adversary, trying to minimize his cost. In each round, the player chooses a probability distribution over $N$ strategies (also termed actions here). After the player has committed to a probability distribution, or mixed strategy as we will say, the adversary picks a cost vector fixing the cost for each of the $N$ strategies.

In round $t = 1, \ldots, T$, the following happens:

- The player picks a probability distribution $p^{(t)} = (p_1^{(t)}, \ldots, p_N^{(t)})$ over his strategies.
- The adversary picks a cost vector $\ell^{(t)} = (\ell_1^{(t)}, \ldots, \ell_N^{(t)})$, where $\ell_i^{(t)} \in [0, 1]$ for all $i$.
- A strategy $a^{(t)}$ is chosen according to the probability distribution $p^{(t)}$. The player incurs this strategy’s cost and gets to know the entire cost vector.

What is the right benchmark for an algorithm in this setting? The best action sequence in hindsight achieves a cost of $\sum_{t=1}^T \min_{i \in [N]} \ell_i^{(t)}$. However, getting close to this number is generally hopeless as the following example shows.

**Example 7.1.** Suppose $N = 2$ and consider an adversary that chooses $\ell^{(t)} = (1, 0)$ if $p_1^{(t)} \geq 1/2$ and $\ell^{(t)} = (0, 1)$ otherwise. Then the expected cost of the player is at least $T/2$, while the best action sequence in hindsight has cost 0.

Instead, we will swap the sum and the minimum, and compare to $L^{(T)}_{\min} = E \left[ \min_{i \in [N]} \sum_{t=1}^T \ell_i^{(t)} \right]$. That is, instead of comparing to the best action sequence in hindsight, we compare to the best fixed action in hindsight. The expected cost of some algorithm $A$ is given as $L_A^{(T)} = E \left[ \sum_{t=1}^T \ell_{a^{(t)}}^{(t)} \right]$. The difference of this cost and the cost of the best single strategy in hindsight is called external regret.

**Definition 7.2.** The expected external regret of algorithm $A$ is defined as $R_A^{(T)} = L_A^{(T)} - L^{(T)}_{\min}$.

**Definition 7.3.** An algorithm is called no-external-regret algorithm if for any adversary and all $T$ we have $R_A^{(T)} = o(T)$.

This means that the average cost per round of a no-external-regret algorithm approaches the one of the best fixed strategy in hindsight or even beats it.

2 The Multiplicative-Weights Algorithm

By the definition it is not even clear that there are no-external-regret algorithms. Fortunately, there are. In this section, we will get to know the multiplicative-weights algorithm (also known as randomized weighted majority or hedge).
The algorithm maintains weights \( w_i^{(t)} \), which are proportional to the probability that strategy \( i \) will be used in round \( t \). After each round, the weights are updated by a multiplicative factor, which depends on the cost in the current round.

Let \( \eta \in (0, \frac{1}{2}] \); we will choose \( \eta \) later.

- Initially, set \( w_i^{(1)} = 1 \), for every \( i \in [N] \).
- At every time \( t \),
  - Let \( W^{(t)} = \sum_{i=1}^{N} w_i^{(t)} \);
  - Choose strategy \( i \) with probability \( p_i^{(t)} = \frac{w_i^{(t)}}{W^{(t)}} \);
  - Set \( w_i^{(t+1)} = w_i^{(t)} \cdot (1 - \eta) \ell_i^{(t)} \).

Let’s build up some intuition for what this algorithm does. First suppose \( \ell_i^{(t)} \in \{0, 1\} \). Strategies with cost 0 maintain their weight, while the weight of strategies with cost 1 is multiplied by \((1 - \eta)\). So the weight decays exponentially quickly in the number of 1’s. Next consider the impact of \( \eta \). Setting \( \eta \) to zero means that we pick a strategy uniformly at random and continue to do so, on the other hand the higher \( \eta \) the more we punish strategies which incurred a high cost. So we can think of \( \eta \) as controlling the tradeoff between exploration (small \( \eta \)) and exploitation (large \( \eta \)).

**Theorem 7.4** (Littlestone and Warmuth, 1994). The multiplicative-weights algorithm, for any choices by the adversary of cost vectors from \([0, 1]\), guarantees

\[
L_{MW}^{(T)} \leq (1 + \eta)L_{\text{min}}^{(T)} + \ln \frac{N}{\eta}.
\]

Setting \( \eta = \sqrt{\frac{\ln N}{T}} \) yields

\[
L_{MW}^{(T)} \leq L_{\text{min}}^{(T)} + 2\sqrt{T\ln N}.
\]

**Corollary 7.5.** The multiplicative-weights algorithm with \( \eta = \sqrt{\frac{\ln N}{T}} \) has external regret at most \( 2\sqrt{T\ln N} = o(T) \) and hence is a no-external-regret algorithm.

### 3 Non-Adaptive Adversary

It seems particularly difficult to analyze the algorithm because the adversary is allowed to react to the player’s choices. It will turn out that this does actually not matter. But as a first step, let us ignore entirely this adaptivity and let us assume that the adversary has to fix the sequence of cost vectors first. We will call this non-adaptive sequence \( \tilde{\ell}^{(1)}, \ldots, \tilde{\ell}^{(T)} \) first. Note that this immediately fixes the probability vectors \( p^{(1)}, \ldots, p^{(T)} \) as well. They are not random anymore.

**Proposition 7.6.** For every fixed non-adaptive sequence \( \tilde{\ell}^{(1)}, \ldots, \tilde{\ell}^{(T)} \) of cost vectors from \([0, 1]\), MW guarantees for every fixed strategy \( i \)

\[
\tilde{L}_{MW}^{(T)} \leq (1 + \eta)\tilde{L}_i^{(T)} + \frac{\ln N}{\eta},
\]

where \( \tilde{L}_i^{(T)} = \sum_{t=1}^{T} \tilde{\ell}_i^{(t)} \) is the sum of costs of strategy \( i \) and \( \tilde{L}_{MW}^{(T)} = \sum_{t=1}^{T} \sum_{i=1}^{N} p_i^{(t)} \tilde{\ell}_i^{(t)} \) is the expected sum of costs of MW.
Proof. Let us analyze how the sum of weights $W(t)$ decreases over time. It holds

$$W^{(t+1)} = \sum_{i=1}^{N} w_i^{(t+1)} = \sum_{i=1}^{N} w_i^{(t)} (1 - \eta \tilde{\ell}_i^{(t)}) .$$

Observe that $(1 - \eta)^{\tilde{\ell}} = (1 - \tilde{\ell} \eta)$, for both $\tilde{\ell} = 0$ and $\tilde{\ell} = 1$. Furthermore, $(1 - \eta)^{\tilde{\ell}}$ is a convex function in $\tilde{\ell}$. For $\tilde{\ell} \in [0, 1]$ this implies $(1 - \eta)^{\tilde{\ell}} \leq (1 - \tilde{\ell} \eta)$.

This gives us

$$W^{(t+1)} \leq \sum_{i=1}^{N} w_i^{(t)} (1 - \tilde{\ell}_i^{(t)} \eta) = W^{(t)} - \eta \sum_{i=1}^{N} w_i^{(t)} \tilde{\ell}_i^{(t)} .$$

Let $\tilde{\ell}_{MW}^{(t)}$ denote the expected cost of MW in step $t$. It holds $\tilde{\ell}_{MW}^{(t)} = \sum_{i=1}^{N} \tilde{\ell}_i^{(t)} w_i^{(t)}/W^{(t)}$.

Substituting this into the bound for $W^{(t+1)}$ gives

$$W^{(t+1)} \leq W^{(t)} - \eta \tilde{\ell}_{MW}^{(t)} W^{(t)} = W^{(t)} (1 - \eta \tilde{\ell}_{MW}^{(t)}) .$$

As a consequence,

$$W^{(T+1)} \leq W^{(1)} \prod_{t=1}^{T} (1 - \eta \tilde{\ell}_{MW}^{(t)}) = N \prod_{t=1}^{T} (1 - \eta \tilde{\ell}_{MW}^{(t)}) .$$

This means that the sum of weights after step $T$ can be *upper bounded* in terms of the expected costs of MW. On the other hand, the sum of weights after step $T$ can be *lower bounded* in terms of the costs of the best strategy as follows:

$$W^{(T+1)} \geq \max_{1 \leq i \leq N} (w_i^{(T+1)}) = \max_{1 \leq i \leq N} \left( w_i^{(1)} \prod_{t=1}^{T} (1 - \eta \tilde{\ell}_i^{(t)}) \right) = \max_{1 \leq i \leq N} \left( (1 - \eta)^{\sum_{t=1}^{T} \tilde{\ell}_i^{(t)}} \right) = (1 - \eta)^{\tilde{\ell}_{\min}^{(T)}} .$$

Combining the bounds and taking the logarithm on both sides gives us

$$\tilde{\ell}_{\min}^{(T)} \ln (1 - \eta) \leq (\ln N) + \sum_{t=1}^{T} \ln (1 - \eta \tilde{\ell}_{MW}^{(t)}) .$$

In order to simplify, we will now use the following estimation

$$-z - z^2 \leq \ln (1 - z) \leq -z ,$$

which holds for every $z \in [0, \frac{1}{2}]$. 

This gives us

\[ \tilde{L}(T) \min \leq (\ln N) \sum_{t=1}^{T} (-\eta \tilde{\ell}(t)) \]

\[ = (\ln N) - \eta \tilde{L}(T) \MW. \]

Finally, solving for \( \tilde{L}(T) \MW \) gives

\[ \tilde{L}(T) \MW \leq (1 + \eta) \tilde{L}(T) \min + \frac{\ln N}{\eta}. \]

## 4 Adaptive Adversary

The above argument works against a non-adaptive adversary. That is, the sequence of cost vectors \( \ell(1), \ldots, \ell(T) \) is fixed before the player does anything. Somewhat surprisingly, the guarantee continues to hold even if the adversary can adapt to the player’s decisions. Note that this way the point of comparison, the best strategy in hindsight, changes depending on the choices made by the player.

**Proposition 7.7.** The multiplicative-weights algorithm, for any (possibly adaptive) choices by the adversary of cost vectors from \([0, 1]\), guarantees

\[ L(T) \MW \leq (1 + \eta) L(T) \min + \frac{\ln N}{\eta}. \]

**Proof.** We will design a non-adaptive adversary that simulates the adaptive adversary. It generates a random but non-adaptive sequence \( \tilde{\ell}(1), \ldots, \tilde{\ell}(T) \) such that \( \mathbf{E} [\tilde{L}(T) \MW] = L(T) \MW \) and \( \mathbf{E} [\tilde{L}(T) \min] = L(T) \min \). By Proposition 7.6, we then have \( \tilde{L}(T) \MW \leq (1 + \eta) \tilde{L}(T) \min + \frac{\ln N}{\eta} \) as so the claim follows.

The non-adaptive adversary internally simulates the game between the algorithm and the adaptive adversary. More precisely, to determine \( \tilde{\ell}(t) \), it performs the following steps. First, it computes \( p(1), \ldots, p(t) \) as chosen by the algorithm if the sequence so far was \( \tilde{\ell}(1), \ldots, \tilde{\ell}(t-1) \). It also draws an imaginary \( \tilde{a}(t-1) \). For \( \tilde{\ell}(t) \) it then uses the exact vector \( \tilde{\ell}(t) \) that the adaptive adversary would use when adapting to \( p(1), \ldots, p(t) \) and \( \tilde{a}(1), \ldots, \tilde{a}(t-1) \).

Observe that this way the two sequences \( \ell(1), \ldots, \ell(T) \) and \( \tilde{\ell}(1), \ldots, \tilde{\ell}(T) \) are identically distributed. This already implies \( \mathbf{E} [\tilde{L}(T) \min] = L(T) \min \). The difference is that \( \tilde{\ell}(t) \) depends on the “real” choices \( a(1), \ldots, a(t-1) \) of the algorithm whereas \( \tilde{\ell}(t) \) depends on the “imaginary” choices \( \tilde{a}(1), \ldots, \tilde{a}(t-1) \).

However, the expected cost of the algorithm in a fixed step \( t \) is the same. To see this, compare the algorithm on the non-adaptive sequence when \( \tilde{\ell}(1) = z(1), \ldots, \tilde{\ell}(t) = z(t) \) to the one on the adaptive sequence when \( \ell(1) = z(1), \ldots, \ell(t) = z(t) \) for any vectors \( z(1), \ldots, z(t) \). The
computed vector $p^{(t)}$ will be the same in both situations because it is deterministic. So, also
the choice of the algorithm is distributed identically on both sequences. (Recall that even the
adaptive adversary cannot choose $\ell^{(t)}$ depending on $a^{(t)}$.) So, writing $\bar{\ell}^{(t)}_{MW}$ and $\ell^{(t)}_{MW}$ for the
respective cost of the algorithm, we have in particular $E[\ell^{(t)}_{MW}] = E[\bar{\ell}^{(t)}_{MW}]$. By linearity of
expectation

$$E\left[\sum_{t=1}^{T} \ell^{(t)}_{MW}\right] = E\left[\sum_{t=1}^{T} \bar{\ell}^{(t)}_{MW}\right] = L^{(T)}_{MW}.$$

\[\square\]
